## Introduction

To evaluate the performance of different normalization methods on the detection of chromatin interaction differences, controlled changes were used. To better control for existing differences in the real Hi-C data, simulated Hi-C datasets were used. The data was simulated using the `hic_simulate` function. For the simulated matrices, the default values were used (see `?hic_simulate`) except for changing the size to be a 250 x 250 matrix. The effect of varying fold changes (1.5 by default) and varying number of controlled changes (500 by default) is investigated.

Fold changes are applied to one of the datasets by upregulating the selected IF if the difference between the datasets is positive. If the difference between the datasets at that point is negative the IF is downregulated by the specified fold change. This method of making changes ensures that the fold change specified is actually realized on the MD plot.

## Bar plots

The bar plots show comparisons of the effect of different fold changes using fixed numbers of controlled changes on different performance metrics.

## Summary

The tables show that the most true differences are detected after joint `loess` normalization compared to the other normalization techniques. `loess` also has the lowest number of false positives among the normalization techniques. With `loess`, differences at smaller fold changes (1.5 and 2) are able to be detected more reliably compared to the other methods and this superiority continues to the higher fold changes though the other methods tend to make up some ground. `ChromoR` performed the worst of the normalization techniques tested while `KR` and `SCN` tended to perform better.

## The effect of introduced number of changes

A specified number of interaction frequencies were increased or decreased to produce a 1.5-fold change.

## Bar plots

Below are bar plots showing comparisons of the different normalization methods over the varying numbers of changes at a fixed fold change for selected metrics.

## Summary

When only a single true difference was introduced at a 1.5 fold change all methods failed to detect it. At all other numbers of introduced differences checked, loess was able to detect the most while also maintaining the lowest number of false positives. KR and SCN again performed better than ICE and chromoR at detecting the true differences.
